Friendship Paradox

Friendship Paradox: Most people have fewer friends than their friends have, on average.

Preferential Attachment Graphs

- The new node linked to old node i preferentially at each time slot

$$P(i = s) = \begin{cases} d_s(t) / (2t - 1) & 1 \leq s \leq t - 1, \\ 1 / (2t - 1) & s = t. \end{cases}$$

with $d_i(t)$ representing the degree of node v_i in time t

- The process can be interpreted from the aspect of graph formation based on the idea of linearized chord diagrams (LCDs).

E-R Random Graphs

- Constructed by connecting every node pair in n nodes with an equal probability p .
- We define $n = t$, $p = \frac{2m}{t-1}$ to both ensure graphs to be connected and better compare with evolving ones.

Definition (Single-step Friendship Paradox)

We define a random nodes v^0 by picking v^0 uniformly from all nodes in G . Then single-step friendship paradox exists in G if the average degree of v^0 's neighbors is larger than the degree of v^0 .

In an evolving network, a node chosen uniformly at random exhibits the phenomenon of single-step friendship paradox with a **higher** probability than that in a non-evolving network.

In an evolving network, a node chosen uniformly at random exhibits the phenomenon of single-step friendship paradox with a **higher** probability than that in a non-evolving network.

- This benefits from the preferential attachment.

Definition (Single-step Friendship Paradox)

We define a random sequence of nodes denoted as (v^0, v^1, v^2, \dots) that results from neighboring node selection based a specified random walk at each step, with the original node v^0 uniformly picked from all the nodes in G . We say that multi-step friendship paradox exists if the sequence can reach the node of higher degree during the process.

Mean hitting rate of reaching the max degree node:

- Evolving networks: $\Omega\left(\frac{1}{\sqrt{t} \log^2 t}\right)$
- Non-evolving networks: $O\left(\frac{\log^2 t}{t}\right)$

**Biased
Random Walk**

- Biased random walk which at each step prefers to select a neighbor with higher degree.
- Particularly, we let the neighboring node v_j of the current node v_i be chosen proportionally to its degree, i.e.,

$$P(v = v_j) = \begin{cases} \frac{d_j(t)}{\sum_{v_k \in N(v_i)} d_k}, & v_j \in N(v_i) \\ 0, & v_j \notin N(v_i), \end{cases} \quad (1)$$

Mean hitting rate of reaching the max degree node:

- Evolving networks: $\Omega\left(\frac{\log \log t}{t^{1/3+\epsilon} \log^7 t}\right)$
- Non-evolving networks: $O\left(\frac{\log^3 t}{t}\right)$
